Abstract

Computer adaptive testing (CAT) is an increasingly common mode of test administration offering improved test security, better measurement precision, and the potential for shorter testing experiences. This paper presents a new item selection algorithm based on a generalized objective function to support multiple types of testing conditions and principled assessment design. The generalized nature of the algorithm permits a wide array of test requirements allowing experts to define what to measure and how to measure it and the algorithm is simply a means to an end to support better construct representation. This work also emphasizes the computational algorithm and its ability to scale to support faster computing and better cost-containment in real-world applications than other CAT algorithms. We make a significant effort to consolidate all information needed to build and scale the algorithm so that expert psychometricians and software developers can use this document as a self-contained resource and specification document to build and deploy an operational CAT platform.

Keywords: computer adaptive testing; computational psychometrics; item response theory

Introduction

The main purpose of computer adaptive testing (CAT) is to build a unique test form for an examinee by choosing test items around their ability on a target construct (Reckase, Ju, & Kim, 2019). In theory, the best form is one that yields a test information function (TIF) that is maximized at the examinee's true level of ability (Babcock & Weiss, 2009) and is best in the sense that it ensures a match between examinee ability and the psychometric characteristics of the items (Chang, 2015). Because true ability varies by individual, this implies a unique test form for each examinee where

test items are carefully curated by a selection algorithm for administration. When item selection is tailored to examinees, adaptive tests provide more information regarding the examinee's ability with fewer items relative to a fixed form test (van der Linden, 2005b; Yao, 2019), are useful to support the measurement of change (Finkelman, Weiss, & Kim-Kang, 2010), and test security is improved as examinees in similarly proctored settings will have forms with different test items when item exposure is well-controlled (Yasuda, Hull, & Mae, 2022).

A challenge in adaptive testing is that true ability is latent and its best indicator, the observed ability, changes as examinees provide responses to new items as they progress through a test. Consequently, an adaptive algorithm iteratively improves its choice of items as more information is provided about the examinee to create the best possible test form (van der Linden & Pashley, 2010). However, some elements within a CAT algorithm remain fixed over the sequence of test items as the latent trait is better revealed. Perhaps parameters within the algorithm may benefit from changing over the test sequence.

Implicit in the description above is that the term "best" is well-understood for item selection (Kingsbury & Zara, 1989) and that some transparent machinery is available to choose those items from a test bank. In fact, "best" can be used differently depending on the test purpose. Therefore, it is key to begin with an operational definition of "best" and then create a mechanism that chooses the best items to uniquely construct a test form for an examinee.

All adaptive algorithms share the common feature that they adapt items on ability, usually on the individual examinee (van der Linden, 2005a), but optionally the algorithm may maximize information near a critical point, such as a cutscore for classification. In this way, CATs minimize the individual error variance and provide greater measurement precision. However, adaptive algorithms can vary in how they define "best" in the sense of choosing the items for administration (Ho & Dodd, 2012). For instance, if there is no test blueprint, then "best" might be considered exclusively on the psychometric properties of the items vis-à-vis the individual tester. If there is a content blueprint with requirements to choose items from different dimensions of that blueprint, then perhaps "best" can be defined to include content characteristics of the items. If both factors are important, then the "best" item is one where the algorithm simultaneously considers the measurement properties of the items and their non-statistical content characteristics at each step.

Perhaps the idea of "best" should not be strictly defined by the capabilities of the algorithm. Test designers should follow theories of principled assessment design (Mislevy & Riconscente, 2006) and the algorithm itself should be able to administer any type of test form developers can imagine, a concept that has been formerly well-articulated (Stocking & Swanson, 1993). In this case, "best" is situationally defined and the algorithm is nothing more than a means to an end and is free to select items from any construct-relevant criteria the test developers wish to impose. This generalized flexibility is one means by which the validity claims regarding test scores arising from CATs can be enhanced (Luecht, De Champlain, & Nungester, 1997; Wise, 2023) and may offer a pathway to support the Design In Real Time approach (Sireci, Suárez-Álvarez, Oliveri, & Zenisky, 2023).

There are many examples of CATs used across the education, certification, licensure, and selection fields that have large computational demands for high volumes of test takers. The Armed Services Vocational Aptitude Battery is one example for military selection (DMDC, 2008), the Smarter Balanced Consortium deploys millions of adaptive tests across states in the U.S. in educational testing (Cohen & Albright, 2014), and the National Council Licensure Examination uses adaptive tests for licensure and certification for medical professionals (Seo, 2017). Some jurisdic-

tions in the U.S. have even codified CATs as a required mode of test administration for educational testing (Florida State Statute §1008.25, 2023; Virginia State Statute §22.1-253.13:3, 2021).

Supporting large volumes of concurrent users requires that “best” also consider the computational choice for an item selection algorithm and its ability to scale on demand. The vast literature on adaptive testing commonly addresses a particular component within the CAT algorithm, such as item exposure (Huebner, Wang, Quinlan, & Seubert, 2015; Leung, Chang, & Hau, 2002; Symptom & Hetter, 1985), ability estimation (Bock & Mislevy, 1982; T. A. Schmitt & Walker, 2010; Spray & Reckase, 1996), information functions (Chang & Ying, 1996), or optimization approaches (Choi, Moellering, Li, & van der Linden, 2016). Less common in the literature are thorough, end-to-end descriptions of the inner workings of an entire CAT ecosystem providing enough detail so that an independent team can identify all necessary psychometric and computational components in a single, self-contained resource. Rather than exact computational details, it is typical to see generalized schemas for item selection (Straetmans & Eggen, 1998; Wainer, Dorans, Flaugh, Green, & Mislevy, 2000). There are a few exceptions where computational details are provided, but such a level of detail is less typical (Belov, Armstrong, & Weissman, 2008; Han, 2018; van der Linden, 2022).

Purpose and Organization

This paper introduces a generalized item selection algorithm that varies in how components within the function contribute to item selection over the sequence of test items with a specific emphasis on building a computationally scalable implementation. The generalized nature of the algorithm permits test requirements related to content balancing, cognitive complexity demands, item enemy targets, types of items administered, psychometric measurement targets, just to name a few. Some specific examples of what this generalized algorithm can achieve include adapting only on ability to minimize individual error, simultaneously adapting on ability and providing content balancing to match requirements defined in a test blueprint, only control for content requirements in which case the test form is linear-on-the-fly (LOFT), limit the algorithm to administer items from a subset of the bank without bifurcating the bank such as when item enemies might exist, administer a collection of items nested within any common grouping structure, flexibly administer operational and experimental field test items spiraled together, and build on-the-fly multistage adaptive forms. Importantly, the underlying algorithm and its code do not need to be altered to achieve any of these variants as customizability is a function of the algorithm itself.

Our specific aim is to achieve four objectives in this manuscript. First, we propose and fully describe the item selection algorithm. Second, we include complete end-to-end requirements for deploying this algorithm so that this document can serve as a self-contained resource with enough detail allowing an expert psychometric and software development team to build an instance of this CAT. Third, we justify the scalability of the algorithm relative to other approaches and propose ways to implement the algorithm to further realize minimal latency at the test-taker level and improved cost-containment in real-world applications. Fourth, we demonstrate the potential of the algorithm with some test trial cases to document its behavior in simulated settings.

The Generalized Item Selection Algorithm

Let the general item selection function for item $j = 1, \dots, J$ for examinee $i = 1, \dots, P$ at step $t = 1, \dots, T$ needed for test feature $g = 1, \dots, G$ be

$$\lambda_{jit} = \pi_{jt} I'_j(\hat{\theta}_{it}) + \sum_{g=1}^G v_{gt} w_{jg} m_{igt} + \sum_{g=1}^G h_g w_{jg} \alpha_{igt}, \quad (1)$$

where the function is a weighted linear composite of three additive components on the right-hand side including 1) the item information function, 2) the value of the content balancing parameter needed to fulfill other test developer features, and 3) a stochastic content parameter to randomly boost and potentially vary the administrative sequence of test items by dimension. Table (1) provides an overview and brief description of the notation used in Equation (1). However, each term in this objective function is fully described in complete detail in the remaining sections.

In this context, the term λ_{jit} is a scalar-valued statistic describing the potential for an item to best fulfill the requirements necessary to meet test form criteria for a given examinee at each iteration of the test process. The maximum value of this objective function, $\max \lambda_{jit}$, is the item with the most potential at step t to fulfill the objectives of the selection algorithm.

Throughout this manuscript, we differentiate between two terms, *algorithmic* details and *decision* details. The term “algorithmic details” is used to mean the specific components in Equation (1) and a “decision detail” is used to mean how an algorithmic component might be implemented. For example, the item information function is an algorithmic component of the objective function. How item information is computed is a decision detail. We also use the term *requirements* and not *constraints* when referring to our algorithm. This is to avoid confusion with terms commonly used in mixed integer linear programming (MILP). In MILP, constraints are used to define a feasible region and a solution must exist within that feasible region. Our approach defines boundaries for test features, and they resemble constraints, but optimization is performed differently.

Parameter	Description
π_{jt}	User-defined importance weight associated with information for the j th item at step t .
$\hat{\theta}_{it}$	Estimated ability for examinee i at step t .
$I'_j(\hat{\theta}_{it})$	Item information function for item j evaluated at the ability estimate for examinee i at step t rescaled to be on same unit space as m_{igt} .
v_{gt}	User-defined importance feature weight associated with dimension g at step t of test blueprint.
w_{jg}	Indicator value linking item j to feature g of a test blueprint.
m_{igt}	Value of content priority index for examinee i at step t for feature g .
h_g	Binary indicator to toggle content sequence parameter on ($h_g = 1$) or off ($h_g = 0$).
α_{igt}	Random draw from a uniform distribution to balance content administration.

Table 1: Notation for CAT Algorithm in Equation (1)

Formal Definition

Equation (1) is useful for general consideration of the idea but lacks some formalities. This section offers a formal definition of the item selection algorithm lending to a more useful computational representation. Let the objective function be

$$\lambda_{it} = f(\pi, \mathbf{I}'(\theta_{it}), \mathbf{W}, \mathbf{m}_{it}) = \pi \odot \mathbf{I}'(\theta_{it}) + \mathbf{W}\mathbf{m}_{it}, \quad (2)$$

where $\pi = (\pi_{1t}, \dots, \pi_{JT}) \in \mathbb{R}_{[0,\infty]}^J$, $\mathbf{I}'(\theta_{it}) = (I'_1(\hat{\theta}_{it}), \dots, I'_J(\hat{\theta}_{it})) \in \mathbb{R}_{[0,1]}^J$, $\mathbf{W} = [w_{jg}] \in \mathbb{R}_{[0,1]}^{J \times G}$ is an attribute indicator matrix where the rows are the test items in the bank and the columns are values linking the j th item with the g th item feature, h_g is a binary indicator, and $\mathbf{m}_{it} = ((v_{1t}m_{i1t} + h_1\alpha_{i1t}), \dots, (v_{GT}m_{iGt} + h_G\alpha_{iGt})) \in \mathbb{R}_{[0,\infty]}^G$. Here the notation $\mathbb{R}_{[a,b]}$ is used to mean a continuous number on the interval $[a, b]$ including endpoints, $\pi \odot \mathbf{I}'(\theta_{it})$ is the Hadamard product yielding a vector of length J , and $\mathbf{W}\mathbf{m}_{it}$ is the ordinary matrix product also yielding a vector of length J . Finally, let $f: \mathbb{R}_{[0,\infty]}^J \times \mathbb{R}_{[0,1]}^J + \mathbb{R}_{[0,1]}^{J \times G} \times \mathbb{R}_{[0,\infty]}^G \rightarrow \mathbb{R}_{[0,\infty]}^J$ be the linear map where the function sends the J -length vector $\lambda_{it} = (\lambda_{1it}, \lambda_{2it}, \dots, \lambda_{Jit})$.

Note that \mathbf{W} has dimensions $J \times G$, meaning a test item can be linked to many different features. In doing so, it is important to normalize the rows in the matrix \mathbf{W} to account for the number of features an item is associated with. Without the normalization, items linked to many features would be more attractive to the item selection algorithm given that the resulting value for λ_{jit} is the row sum over all columns in this matrix. The elements of \mathbf{W} before normalization assume values of $w_{jg} = 1$ if item j is associated with feature g and 0 otherwise. Then, the original rows of the matrix \mathbf{W} , denoted as $\mathbf{w}_j = (w_{j1}, \dots, w_{jG})$, are normalized where each element becomes $w_{jg}^* = w_{jg} / \sum_{g=1}^G w_{jg}$ and $\sum_{g=1}^G w_{jg}^* = 1$.

Equation (2) could treat $\pi_{jt} = \pi \forall j, t$ as a constant information weight applied in the same way to all items. However, its treatment as a vector offers broader applications where different weights for information could be applied to vary over some types of items and this weight could then also vary over t . This is useful in situations where the psychometric properties of items could be exploited as weights. For example, it could be useful to make use of the item-specific variances, σ_j^2 , and use their reciprocals as weights such as $\pi = (1/\sigma_1^2, \dots, 1/\sigma_J^2)$ mimicking weighting strategies used in survey design for complex samples (Wolter, 1985). Though interesting, some caution on this strategy is needed as this would cause the algorithm to prefer items with smaller standard errors and lead to some potential item overexposure. A second potential use of the vector could be to achieve a quasi a -stratification approach (Huebner, Wang, Daly, & Pinkelman, 2018) where $\pi_j = a_j^{-1}$ is set to the reciprocal of the a -parameter causing the algorithm to use items with smaller slopes more often in early item administration. Last, a third option could be to set $\pi_j = 1$ for operational items and then set $\pi_j = 0$ for experimental field test items. In this way, the algorithm offers an embedded field test mechanism where trial items are administered alongside operational items into randomly seeded positions. Fixing field test items into specific positions may require a post hoc business rule as Equation (2) is primarily intended for item selection and not specifically for item position.

Optimization Approach

The goal of the objective function is to yield a value denoting which item is best for test administration. Our objective function and test requirements could be formulated as a MILP problem as

commonly used in the automated test assembly literature (Becker, Weirich, Goldhammer, & Debeer, 2023; van der Linden, 2005c; Xu, Wang, Cai, & Tu, 2021). MILP has been demonstrated for the shadow test method (Choi et al., 2016) and the weighted deviation method (Stocking & Swanson, 1993). However, MILP is computationally expensive, challenging to implement in applied settings, and is not guaranteed to find an optimal solution (Zheng, Nozawa, Gao, & Chang, 2012). Additionally, the mathematical complexity of linear programming almost always requires an external commercial or open-source optimizer (Luo, 2020; van der Linden, 2022) instead of code written and owned by the development team building the CAT engine. This adds another layer of difficulty for development teams since they must continuously adapt and maintain code to be compatible with the potential for changing application programming interfaces (APIs) of external optimizers to ensure uninterrupted live testing.

Here we propose optimization in a different way using a sort-and-search algorithm. In our approach, the input values in $f(\boldsymbol{\pi}, \mathbf{I}'(\boldsymbol{\theta}_{it}), \mathbf{W}, \mathbf{m}_{it})$ are treated as known, fixed quantities for computing the elements of λ_{it} , thus allowing us to directly compute Equation (2) and find the maximum value in the finite set λ_{it} , or $\max \lambda_{it}$. When λ_{it} is sorted in descending order, the first item in the vector is best for selection in the sense that it contributes best to the objectives defined by the test developer.

This approach to optimization frames Equation (2) into the family of so-called heuristic algorithms for test assembly (Luecht, 1998; Stocking & Swanson, 1993). Consequently, this effort joins the prior body of research by sharing the common feature of maximizing an objective function at each of the $t = 1, \dots, T$ steps choosing one item at a time until termination criteria are satisfied. Our effort offers three extensions to prior work in the following ways. First, a distinguishing feature of Equation (2) is the vectorization of user-defined importance weights included directly within the objective function. To our knowledge, this is the first effort to vectorize these weights allowing them to vary by item, item position, information, and content feature and manipulation of these weights is how we achieve different test formats such as item adaptive, multistage adaptive, LOFT, a -stratification, or field test spiraling within a unified framework. In this way, the user-weights may themselves assume the role of random variables that vary over the sequence of test items rather than simply being fixed constants. Second, elements in the attribute linkage matrix \mathbf{W} are normalized allowing items to be either nested within a single attribute or to be crossed with multiple attributes without causing items crossed with multiple attributes to be more attractive to the algorithm than those linked to a single attribute. This extends the ideas in Luecht (1998) where item linkages to test features in that work are binary, which could be altered to achieve a similar outcome, but we make this explicit in our algorithm. Last, we configure the term α_{igt} to accelerate and/or vary the algorithm's preference for certain items in a manner that differs uniquely from other efforts. Additionally, we offer some decision details that may improve computational efficiency in the context of this algorithm such as the proposed information switching strategy, the sufficiently adaptive concept, and a way to reduce the search space for faster item selection.

User-Defined Configuration Weights

This section offers a formal definition of the user-defined importance weights. These weights, combined with different ways to configure the content priority index, are what make Equation (2) configurable to support different test designs. Pragmatically, they are simply ways to balance the importance between the statistical properties of the items and their non-statistical content char-

acteristics. Examples of their application are provided in the simulation section showcasing how different configurations yield different adaptive test outcomes.

Formally, the values for π_{jt} and v_{gt} are scalar-valued importance weights defined as $\mathbb{R}_{0 \leq \omega \leq \infty} = \{\omega \in \mathbb{R} | 0 \leq \omega \leq \infty\}$ which is used to mean importance weights in the set $\omega \in \{\pi_{jt}, v_{gt}\}$ can be zero or any positive real number. Note that importance weights of $\pi_{jt} = 0 \forall j, t$ cause the algorithm to be either driven entirely by content requirements (linear-on-the-fly) and the most primitive form of an adaptive algorithm is a special case of Equation (1) when $\{v_{gt}, h_g\} = 0 \forall g, t$ and $\pi_{jt} = 1 \forall j, t$ adapting only on ability and ignoring content.

The most obvious choice for the weights is for them to assume values of 0 or 1 effectively turning the different components of the algorithm off and on, respectively. However, they are real numbers so that they can reflect gradations of importance as decided by test developers. For instance, if $v_{gt} < \pi_{jt}$, for any particular j and g then more weight is given to the psychometric measurement properties of the items than their content balancing feature. If $\pi_{jt} < v_{gt}$, then more weight is placed on the content features than the psychometric properties of the items. If $\pi_{jt} = v_{gt} \forall j$ and g , then equal emphasis is placed on both. Finally, note that the feature weights are subscripted, indicating they are configurable by content feature giving the algorithm greater preference in some feature areas and less in others.

It is also feasible to construct weights as a function of multiple variables. For instance, the information weights could be a function of a weight idiosyncratic to the j th item and to its t th position in the test, such as $\pi_{jt} = \pi_j \times \pi_t$. For example, perhaps π_j is set to vary over j and then information at earlier phases in the test might be weighted less than information later in the test as measurement error decreases using the reciprocal of the conditional standard error of measurement (squared), $\pi_{it} = 1/\sigma^2(\hat{\theta}_{it})$. In this way, information in the objective function varies with increasing t as in $\pi_t < \pi_{t+1}, \dots, < \pi_T$ such that the contribution of information increases within the objective function proportional to the rate at which measurement error decreases.

Hence, the weights are simply inputs to the objective function that are relative to each other. If $\pi_{jt} = 1$ and $v_{gt} = 1$ equal weight is placed on ability and content in the objective function as it chooses items. Alternatively, the values of $\pi_{jt} = 2$ and $v_{gt} = .5$ might be used to weight information with greater importance than blueprint features or conversely, $\pi_{jt} = 1$ and $v_{gt} = 3$ places more weight on feature requirements than on ability in the objective function.

Methods for Adapting on Examinee Ability

The first term in Equation (2) is the item information function used to adapt on examinee ability. This is typically done when items are drawn from a calibrated item pool and the item information function is evaluated at $\hat{\theta}_{it}$ to determine the next best candidate item (Chen, Ankenmann, & Chang, 2000; Han, 2009). Achieving this can be accomplished using multiple approaches as noted below.

One of the greater challenges in CAT is that $\hat{\theta}_{it}$ early in the test is a poor approximation of the true latent trait given that the estimate is based on a small subset of test items (Chen et al., 2000). That is, for initial item selection we effectively have no information regarding the examinee's true ability. However, under suitable regularity conditions with more items administered at each additional step t , the observed estimate is consistent and converges in probability to its true value, θ_i , $\lim_{t \rightarrow \infty} \Pr(|\hat{\theta}_{it} - \theta_i| > e) = 0$ (Chang, 2015). For this reason, evaluating the item information function at the point estimate $\hat{\theta}_{it}$ early in the test may prove less than ideal because it is swamped

with measurement error.

However, as more items are administered, perhaps $\hat{\theta}_{it}$ may prove useful as a plug in estimator for computing information. This suggests a possible switching strategy could be employed to account for the uncertainty in the ability estimate early in the test but then switch to a method that directly uses the point estimate later in the test. Below we describe approaches for computing item information and then describe how switching between them could be an advantage to balance computational overhead with statistical precision.

Maximum Fisher Information

The item information function in item response theory (IRT) for binary items is

$$I_j(\hat{\theta}_{it}) = D^2 a_j^2 \left[\frac{(\text{Pr}_j(\hat{\theta}_{it}) - c_j)^2}{(1 - c_j)^2} \right] \left[\frac{1 - \text{Pr}_j(\hat{\theta}_{it})}{\text{Pr}_j(\hat{\theta}_{it})} \right], \quad (3)$$

where $\text{Pr}_j(\hat{\theta}_{it})$ is the probability of response from a 3-parameter logistic model given the triplet of $\{a_j, b_j, c_j\}$ denoting the IRT parameters of item slope, item location, and item guessing, respectively (Lord, 1980). The maximum Fisher information (MFI) computes item information from $\hat{\theta}_{it}$ at each step of the algorithm and selection may occur by choosing the item with the largest MFI given $\hat{\theta}_{it}$ (Chang & Ying, 1996).

Integrating Over the Information Function

A second option is to account for the uncertainty in the point estimate and calculate information averaged over the function as

$$I_j(\tilde{\theta}_{it}) = \int_{\hat{\theta}_{it}-\delta_t}^{\hat{\theta}_{it}+\delta_t} D^2 a_j^2 \left[\frac{(\text{Pr}_j(\theta) - c_j)^2}{(1 - c_j)^2} \right] \left[\frac{1 - \text{Pr}_j(\theta)}{\text{Pr}_j(\theta)} \right] d\theta. \quad (4)$$

The limits for integration can be formed using confidence intervals from the conditional standard errors, $\sigma(\hat{\theta}_{it})$, as $\delta_t = \Phi^{-1}(p)\sigma(\hat{\theta}_{it})$ where $\Phi^{-1}(\cdot)$ is the inverse of the normal cumulative distribution function and p is the nominal coverage probability (Veerkamp & Berger, 1994).

Kullback-Leibler Information

A third approach is via the Kullback-Leibler information method (Cover & Thomas, 1991), who informally describe this as a distance metric between two distributions. Its application in adaptive testing for binary items is

$$KL_j(\hat{\theta}_{it}) = \int_{\hat{\theta}_{it}-\delta_t}^{\hat{\theta}_{it}+\delta_t} \sum_{l=0}^1 \log \left[\frac{\text{Pr}(x_j = l|\theta)}{\text{Pr}(x_j = l|\hat{\theta}_{it})} \right] \text{Pr}(x_j = l|\theta) d\theta, \quad (5)$$

where x_j is the response to item j and θ is true ability (Belov & Armstrong, 2011; Chang & Ying, 1996; Chen et al., 2000). Chang and Ying (1996) choose $\delta_t = \frac{p}{\sqrt{t}}$ where p is chosen to reflect

a nominal coverage probability and justify an impressive implementation relying on the well-documented asymptotic properties of the estimator where the integration limits become smaller with increasing t . Our implementation is similar, but instead of using $\frac{p}{\sqrt{t}}$, we draw the limits of integration using δ_t in the same way described for Equation (4).

Sufficiently Adaptive Information Strategy

It is generally true that adaptive algorithms do not require many items to stabilize near the final ability estimate. In many cases, the test is long simply to administer items representing all areas of the test blueprint, but the ability estimate may have stabilized at some point much earlier in the test. Hence, $\hat{\theta}_{it}$ might not change much after some point in the test. If so, one possible consideration is to form provisional values for $\hat{\theta}_{it}$ only up to step t of the test, where t is some point of stability such as $|\hat{\theta}_{it} - \hat{\theta}_{i,t-1}| < \epsilon$ where ϵ is some user-defined tolerance. Then, from step $t+1$ to the end of the test, plug in the last provisional $\hat{\theta}_{it}$ obtained and from this point forward items are chosen only based on their content requirements fixing information at $\hat{\theta}_{it}$. Once the examinee completes all required operational responses, generate a final $\hat{\theta}_{iT}$ using all item responses. This option would save the overhead associated with computing ability estimates and also with item information and would result in zero latency for the examinee from steps $t+1$ to T as the entire batch of remaining items needed to fulfill blueprint requirements can be immediately determined and sent to the examinee's local machine.

Information Switching Strategy

The KL procedure and the method for averaging over the information function have greater computational expense than directly computing the MFI as they both involve an integral. However, they make better use of the uncertainty in the estimate than the MFI which uses the noisy point estimate. Balancing the two ideas suggests a trade-off approach where one could rely on the asymptotic properties of the estimator and begin early item selection with either the more expensive KL or averaging functions for some initial item selection and then later in the test rely more on the point estimate for computing information.

This idea is originally credited to Chang and Ying (1996). However, our understanding of their approach is that they compute Equation (5) over all items for all values of t . However, with increasing t the limits of integration decrease around the observed estimate, thus treating the observed score as a better estimate at each step. This remains computationally expensive as each step still involves evaluating the integral over all items. Just to paint a quick picture, approximating Equations (4) or (5) using 10 quadrature points, for a 50-item test, with 50,000 examinees, in a test bank of 500 items involves 12,500,000,000 total evaluations!

An efficient computational alternative, but theoretically consistent approach, would be to switch to the MFI from either the KL or the average information function after a fixed number of items is administered given the asymptotic expectations for $\hat{\theta}_{it}$. For example, we might initially compute item information using KL for t steps and then switch to the MFI or, rather than depending on fixed t , switch to the MFI after reaching a desired level of precision.

The notation $I_j(\hat{\theta}_{it})$, $I_j(\tilde{\theta}_{it})$, and $KL_j(\hat{\theta}_{it})$ is used to describe different ways to compute

information for item j . This is useful to denote the differences in the approach. Going forward, we now generically use $I_j(\hat{\theta}_{it})$ to describe a method for computing information and describe in narrative which approach is used simply for the convenience of notation.

Content Balancing

The second and third components of the algorithm are related to the content targets to be administered if a test blueprint exists. This component is often critical to support claims of construct validity from an adaptive test. While the term *content balance* is common, it is perhaps more suitable to refer to them as *feature requirements* as the function in Equation (6) can manage an array of test feature configurations. These components provide the framework by which expert test developers can appropriately define the construct to be measured and then implementation via the following priority index ensures the test form balances both the psychometric and construct-relevant components simultaneously. Others have proposed managing feature requirements alongside psychometric information within the objective function (Luecht, 1998; Mao & Xin, 2013; Stocking & Swanson, 1993) and this algorithm aligns with that notion in spirit but differs in how it is parameterized to achieve this objective.

The first content component described here is an index that determines which aspects of the test blueprint should be prioritized at each step while the second component is intended to introduce some randomization such that items have a “boost” to ensure the forms reach their blueprint minimum or maximum expectations.

Content Index

The content balancing *priority index* parameter is defined in Equation (6), which contributes to the objective function at step t . The term priority index is used to mean that the resulting value contributes to the item selection function adding some priority to improve the chance that item j associated with feature g will be chosen at step t according to

$$m_{igt} = \begin{cases} 1 + \frac{N_{lg} - n_{igt}}{N_{lg}} & \text{if } n_{igt} < N_{lg} \\ \frac{N_{ug} - n_{igt}}{N_{ug} - N_{lg}} & \text{if } N_{lg} \leq n_{igt} < N_{ug} \\ -p & \text{otherwise.} \end{cases} \quad (6)$$

The values N_{lg} and N_{ug} represent minimum and maximum values for the g th feature. Hence, they are considered boundaries for a particular test feature and are used to mean the range of items on the test form necessary to fulfill that requirement, and the value n_{igt} is the number of items with feature g that have been administered to examinee i up to step t .

The value of m_{igt} initiates at 2 $\forall g$ when $n_{igt} = 0$ and the value approaches unity as $n_{igt} \rightarrow N_{lg}$. Once a test feature is satisfied by meeting its minimum requirements (i.e., when $n_{igt} = N_{lg}$), the function of m_{igt} resets to 1 and then the value approaches 0 as $n_{igt} \rightarrow N_{ug}$. The parameter includes a penalty once the algorithm achieves the maximum, thus lowering the algorithm’s preference to use items with this attribute in future selections. This penalty value p might be $p = 1$ or perhaps a larger value so that when $N_{ug} = n_{igt}$, an item associated with feature g is not eliminated from potential use, but p makes m_{igt} negative causing items with that feature to appear at the tail end

of λ_{it} , making them very unlikely for selection. Hence, the larger the value for p , the more it is pushed to the end of λ_{it} .

The priority index operates so that items below their test requirement minimum always have a larger contribution to the objective function than items between their minimum and maximum. That is, items are most attractive to the algorithm when they are below their minimum blueprint requirement and decrease in attractiveness as they approach their maximum. The success of the algorithm in form building concerning these requirements will depend on item availability in the bank and blueprint reasonableness. In situations where either of the two may present limitations, the algorithm would proceed with item selection in real time without disrupting the examinee's test experience given that the penalty on items leading to blueprint violations lowers their rank in λ_{it} , making those items unlikely candidates, not impossible candidates. A well-known concept in optimization that could be very useful with our proposed approach is that of a look-ahead algorithm, which has been applied in the context of heuristic CAT algorithms with evidence for mitigating content violations (Li, Zhang, & Chang, 2019). Applications of look-ahead with our proposed heuristic should be further explored.

Notably, the matrix \mathbf{W} is what establishes linkages between items and their corresponding m_{igt} . Items can be nested in a single feature or they can be partially linked across multiple features. In this way, if each item in the test bank is a member of one and only one content feature, then the constraint CAT (CCAT) of Kingsbury and Zara (1989) is a special case of the approach we implement. If an item belongs to multiple content features, then this approach is closer in principle to other ways in which content balancing might occur with items containing multiple content features that are not mutually exclusive (Segall & Davey, 1995; Stocking & Swanson, 1993).

These blueprint boundaries allow for variability in the nature of the test form at the subtest level, although an overall test length feature is implemented. For instance, we could enforce a total test length of N , but how a form reaches N could vary for examinees at the subtest level. In this way, examinees' i and i' would both have tests of length N . But, they would have different numbers of items at the subtest level making up that total test length. If every test is expected to be the same in terms of length at the subtest level, then $N_{lg} = N_{ug}$ would create tests with different items, but with the same number of items at each lower level.

Content Sequence Balance Parameter

The term m_{igt} in the objective function could cause for the algorithm to be somewhat deterministic and more systematically prefer items with larger values of m_{igt} . To potentially mitigate this effect, the term α_{igt} is introduced as a stochastic parameter to randomly vary the preference of the algorithm for different areas of the content as the test progresses. This parameter adds a small stochastic component to the function at each iteration of the test which has the effect of randomly varying the chances for an item with feature g of being selected at step t .

Approaches such as the modified multinomial model have been proposed to deal with the effects of predictable sequencing (Leung, Chang, & Hau, 2003). Our approach is to add a small stochastic component to the content priority index as $\alpha_{igt} = u_{igt}$ if $\gamma < m_{igt}$ and 0 otherwise where $u_{igt} \sim U(0, 2)$. Note that we draw from $U(0, 2)$ to be commensurate with the values produced by the priority index, m_{igt} . The term γ can assume different values with different meaningful consequences. One option is to set $\gamma = 0$, effectively causing the algorithm to randomly prioritize different blueprint features until any given feature reaches its blueprint maximum. A second option

is to set $\gamma = 1$, causing the algorithm to accelerate its preference for items associated with a content feature below its blueprint minimum. In this way, it offers some assurance that content feature minimums are met with higher priority than feature maximums. A third option is to set $\gamma = u_{igt}$. In this variant, as m_{igt} tends to 0, the probability that u_{igt} adds to the priority index also decreases given that $\Pr(u_{igt} < m_{igt}) = \frac{m_{igt}}{2}$ from properties of the uniform cumulative distribution function. In this way, the algorithm will tend to boost values for features with larger values of m_{igt} .

Establishing a Common Metric Space

Both $I_j(\hat{\theta}_{it})$ and m_{igt} are unique metrics on a different scale. However, the linear composite in Equation (2) requires these vectors to share a common metric space. This normalization is achieved using feature scaling, which yields $I'_j(\hat{\theta}_{it}), m_{igt} \in \mathbb{R}_{[0,1]}$. This does not equate the metrics in the psychometric sense. Instead, the normalized values ensure they both contribute a measure of distance and magnitude in the same way in the objective function. Without this normalization, the range of values and distance between them would contribute unequally to the final result. We use min-max feature scaling for each term and the information function, for example, is rescaled as $I'_j(\hat{\theta}_{it}) = \frac{I_j(\hat{\theta}_{it}) - I(\hat{\theta}_{it,\min})}{I(\hat{\theta}_{it,\max}) - I(\hat{\theta}_{it,\min})}$ where $I(\hat{\theta}_{it,\max})$ and $I(\hat{\theta}_{it,\min})$ denote the maximum and minimum item information functions of all items evaluated for examinee i at step t , respectively. This rescaling is similarly applied to m_{igt} .

Exposure Control

Item exposure control is perhaps one of the most widely studied topics in CAT. Here, we limit consideration to only two methods for implementation in our work, but other methods could easily be incorporated as decision variables for building a CAT engine. The first approach requires no prior knowledge about the items or the population of examinees and is simple to implement. The second is an IRT-based approximation to prevent items with large a -parameters from being selected too often. We acknowledge that the Sympton-Hetter method (Sympton & Hetter, 1985) is an important exposure control method in the CAT literature. Its implementation requires some work to establish an exposure control parameter whereas the randomesque requires no prior knowledge or exposure limits on items. For this reason, we focus on the two methods below, but the Sympton-Hetter method could very easily fit into our algorithmic framework.

Randomesque Approach

The randomesque approach is implemented by computing the value of λ_{jit} for all items in the bank at $\hat{\theta}_{it}$ which forms a vector, sorted in descending order, $\text{sort}(\lambda_{it}) = (\lambda_{1it}, \lambda_{2it}, \dots, \lambda_{Nit})$ where N is the number of (remaining) items in the bank. In this way, the first item in the vector is best suited to meet test developer requirements and the final item in the vector is least suited. Implementation begins by choosing a value $w \in \{1, 2, 3, \dots, N\}$ and randomly choosing one item from the ordered subset $\{\lambda_{1it}, \lambda_{2it}, \dots, \lambda_{wit}\}$. If $w = 1$, the algorithm always chooses the top, best item, and if $w = N$ the algorithm is effectively taking a random draw from all available items in the bank. Pragmatically, setting $w = 5$ (or approximately so) ensures some balance between

randomization and selection of the best next item (Georgiadou, Triantafyllou, & Economides, 2007; Kingsbury & Zara, 1989). This approach mitigates the potential for individuals in similar settings to engage in answer copying since items are partially random even for those with similar ability estimates.

The Impact of Item Slopes

All things being equal, items with large a -parameters provide the most psychometric information conditional on θ and algorithms using IRT-based information functions are likely to overexpose those items (Hau & Chang, 2001). Some approaches consider stratification methods to form bins such that items with smaller slopes are administered earlier in the test and items with larger slopes would be administered later (Huebner et al., 2018). Our algorithm supports a -stratification using the reciprocal of the a -parameters as weights as described under Equation (2). Here we propose a simpler method to minimize the exposure risk of items with large a -parameters by provisionally setting $a_j = a \forall j$ as a common pseudo-value only when computing the item information for purposes of item selection. That is, we use this approximation in item selection but use the estimated (actual) a -parameter when generating ability estimates, both provisional and final. This approximation on the a -parameter is one additional exposure control parameter that mitigates the overexposure of highly informative items in certain populations with similar abilities.

Provisional Scoring Options

A CAT progressively updates $\hat{\theta}_{it}$ after a response is submitted to each new item (Wang & Vispoel, 1998). With IRT, this is generally based on concepts of maximum likelihood estimation (MLE) or Bayesian methods (Bock & Mislevy, 1982; Spray & Reckase, 1996), with the latter being preferred. The challenge with MLE scoring in CAT is that ability estimates cannot be provided for response strings with perfect answers or completely wrong answers as the likelihood function has no maximum. Some tricks can be implemented for MLE methods to adjust score strings or to supplement the response with a fake item response, sometimes referred to as “fences” (Han, 2016). Instead, Bayesian methods do not suffer from this same problem and can be used to generate ability estimates in a broader case of scenarios.

Termination Criteria

Termination of the algorithm may occur under multiple conditions (Babcock & Weiss, 2009), three of which are noted here. The first option is to stop when $\sigma(\hat{\theta}_{it}) \leq \varepsilon$ where ε is a user-defined tolerance for stopping. A second option is when the provisional ability stabilizes as in the sufficiently adaptive strategy, $|\hat{\theta}_{it} - \hat{\theta}_{i,t-1}| \leq \varepsilon$. Or a third option is to stop once the algorithm has administered a fixed number of items. The first two are related to the measurement precision and the third option may be used when feature requirements need to be satisfied before stopping.

Item Selection Process

With all individual components of the algorithm now described, we can provide a high-level schema for item selection as a set of steps as shown in Algorithm (1).

Algorithm 1 Procedural Schema for CAT Algorithm

Input: Choose initial item j from bank and administer to examinee i at step $t = 0$.

- 1: Form a provisional ability estimate after the examinee responds, $\hat{\theta}_{it}$.
 - 2: Update m_{igt} and α_{igt} based on item administered at step t and then set $t := t + 1$.
 - 3: Recompute $I'_j(\hat{\theta}_{it})$ given new estimate, $\hat{\theta}_{it}$.
 - 4: Compute λ_{it} using Equation (2) for the remaining items in the bank excluding previously administered items.
 - 5: Sort vector λ_{it} in descending order.
 - 6: Apply an exposure control procedure and select one item from λ_{it} .
 - 7: If termination criteria are satisfied, stop. Else, return to (1).
 - 8: After test termination, generate final $\hat{\theta}_{iT}$ for reporting.
-

Considerations for Algorithm Scalability

Scaling adaptive algorithms is a well-known practice among those building software applications for large-scale operational use such as the freeze policy (Choi et al., 2016), prioritized searches (Luecht, 1998), or generalized techniques for algorithms in psychometrics (Doran, 2023). Choi et al. (2016) explore an improved computation of the shadow test and make the claim that cloud-based infrastructures for computing are “scalable without limit” (p. 470). This is true in the sense that cloud-based structures provide virtually limitless access to fast computers. This is untrue in the sense that it comes with increasing monetary cost, and when building operational environments for industry, that monetary cost indeed has limits. Consequently, it is important to find the best algorithm for computing and only then pass that into larger cloud-based systems and we offer some caution on viewing cloud-based environments as a panacea for large-scale computing without first critically evaluating the scalability of the algorithm.

The psychometric literature commonly reports simulation runtimes to justify an algorithm or particular computational approach. While there is some value in these timings, we do not follow this practice here. First, these reported runtimes are idiosyncratic to the machine used in the simulation and only reflect that implementation, limiting its potential generalizability. More importantly, time complexity using Big \mathcal{O} is the *de facto* measure by which an algorithm’s ability to scale is evaluated (Chivers & Sleightholme, 2015). MILP algorithms have a time complexity of $n^n 2^{\mathcal{O}(n)}$ (Dadush, Eisenbrand, & Rothvoss, 2023) but quicksort algorithms have complexity $\mathcal{O}(n \log(n))$ (Shujaat, 2022), where n is the collection of inputs used for the model. Hence, all things being equal, quicksort will scale better than MILP. This does not guarantee our approach will have a faster runtime than MILP as timing depends on implementation. It does mean, that all things being equal, our algorithm will scale better and is more likely to have a faster runtime with comparable implementation strategies. On balance, MILP solvers are substantially improv-

ing (Koch, Berthold, Pedersen, & Vanaret, 2022; Luo, 2020) but the runtimes for even the most popular solvers such as CPLEX remain an open question (IBM, 2023).

It is also important to state that any runtimes observed in simulation settings are well-controlled environments. Real-world servers are hit with large numbers of simultaneous users in live testing in unpredictable ways. Cloud computing structures manage large traffic and computing volumes via “elastic load balancing”, which dynamically causes additional server instances to be used when placed under high demand. This would permit any number of CAT algorithms to seem fast but at the additional monetary cost associated with additional servers needed to support larger computational demands.

Equation (1) simultaneously computes the information function and the content priority index at each step over all items in the bank for each examinee to provide the overall value of λ_{jit} . It is already an efficient implementation given that we treat the inputs as fixed and the values for λ_{jit} are directly realized. However, computing information for all J items in Equation (1) has some computational cost and the sorting algorithm itself has cost. Both of those issues can be addressed to reduce the search space and improve computational speed. As a brief aside, one fundamental difference between our approach and the shadow test is our computational cost is limited to the selection of only the next item needed to satisfy requirements. The shadow test builds an entire form of items at each step that must satisfy all constraints but then chooses only one item from that form at each step.

We begin with the notion that realizing scalability is not a function of bigger computing environments, per se. The first objective is to analyze the complexity of the algorithm and then make use of distributed computing concepts or cloud-based structures for faster computing. Hence, we could make use of two common ideas. One could be to precompute values of information for all items at fixed increments of θ and use a precompute, store, and recall approach to create a lookup table. This could be useful, but given that $\theta \in \mathbb{R}$, these values would never be exact for the examinee. Another option is to use parallel processing and distribute the computing of information for J items over multiple cores. This has significant potential, but the split, apply, combine problem brings with it some overhead of reassembling components and this should be evaluated (Wickham, 2011).

A Feasible Computational Approximation with Reduced Inputs

Because the algorithm’s scalability is proportional to its inputs, finding ways to reduce that number will yield improved performance (Doran, 2023). Here we describe an option to reduce the number of inputs for computational scaling. Our proposed computational option is to compute λ_{jit} in smaller components instead of simultaneously over the entire search space. Those steps could be outlined as two steps. First, compute the value of the function based initially on the content features over all J items in the bank $\lambda_{jit}^1 = \sum_{g=1}^G v_{gt} w_{jg} m_{igt} + \sum_{g=1}^G h_g w_{jg} \alpha_{igt}$. Following this step, form a subset by choosing an element in $s \in \{1, 2, \dots, J\}$ and sort giving the ordered subset $\lambda_{it}^1 = (\lambda_{1it}^1, \lambda_{2it}^1, \dots, \lambda_{sit}^1)$ and then compute information only for items in λ_{it}^1 giving the result $\lambda_{jit}^2 = \pi_{jt} I'_j(\theta_{it}) + \lambda_{jit}^1 \forall j \in \{1, \dots, s\}$. Then, sort values based on λ_{jit}^2 and implement an exposure control approach to choose one item from the smaller set in the new space.

This approximation significantly reduces the computational overhead relative to the more costly component (i.e., the information function) by reducing the space over which it is computed. Specifically, we now compute item information only for s items at each step rather than over all J items,

and when $s \ll J$ the cost savings is substantial. Recall that in the information switching section, we note the 12,500,000,000 total evaluations when computed over a bank of 500 items. Suppose instead that $s = 20$ using this strategy, then the total number of evaluations is reduced to 500,000,000. Additionally, the sort algorithm considers only s inputs and not J . Consequently, the idea realizes two computational cost savings. However, this approach implicitly places greater emphasis on the content features of the test than the measurement properties. There could be items with larger values for information outside the set of λ_{jit}^2 that would be ignored with smaller values for s .

If the content features are not used by the algorithm for choosing items, an approximation to reduce the search space only based on the item measurement properties could be to initially compute the item information for all items in the bank. Then, after t steps, use an approximate b -matching procedure (Han, 2018) to compute the item information function only for the subset of items in some range of the provisional ability estimate. The b -matching process is equivalent to using the item information with the Rasch model, but with more general IRT models this would only be an approximation to reduce the search space.

To illustrate, consider that an initial ability estimate is obtained after administering t items, $\hat{\theta}_{it}$. Now, because items and examinees are on the same scale, locate items in the bank where $b_j \in \{\hat{\theta}_{itl}, \dots, \hat{\theta}_{itu}\}$ where the terms l and u are used to mean some lower and upper boundaries around the provisional ability. Then, compute information only for items within this space for the next item selection. This technique also implicitly assumes a common a -parameter and would also help with exposure control.

It could be possible to even further speed up this two-step process using the partial adaptive information strategy suggested. In Step (1) update λ_{jit}^1 as described above. Then, in Step (2), recall the stored values of $I'_j(\hat{\theta}_{it})$ and use those to update λ_{jit}^2 . This avoids having to recompute $\hat{\theta}_{it}$ and $I'_j(\hat{\theta}_{it})$, and it would be possible to immediately determine all remaining items to be administered given that we know what aspects of the blueprint need to be satisfied.

Demonstrating the Model Under Variable Conditions

Some behaviors of the algorithm using a simulated item bank and blueprint are provided in this section. Because the algorithm is designed to be generalizable to various testing conditions, we can only provide a few reasonable permutations to explore. For this reason, we have also provided a complete testing environment for this algorithm in a web-based tool where all simulations and ideas expressed in this manuscript can be independently verified or users can test their own unique item banks, blueprints, and requirements to further explore the ideas discussed. The web-based application is available at https://catsim.shinyapps.io/humrro_cat_engine/.

Simulated Data

The following simulations are based on an item bank of 1000 items from a 2-parameter logistic model with a -parameters generated from $a_j \sim U[.5, 1.5]$ and $b_j \sim U[-4, 4]$. Items are equally assigned to one of four content features and a blueprint (BP) with minimum (N_l) and maximum (N_u) values as in Equation (6) is created as provided in Table (2). This yields 250 items per dimension with item parameters uniformly distributed within each dimension.

Dimension	Minimum (N_l)	Maximum (N_u)
1	5	15
2	5	20
3	5	10
4	5	15

Table 2: Blueprint for Simulation

The simulation generates 100 replicates at each true value of θ_q between $q = \{-3, -2.5, \dots, 3\}$ in increments of .5 for a grand total 1,300 replicates. Using this uniform distribution permits us to capture and report the root mean squared error and the bias at each θ_q . The observed response to each item is generated by first computing the true probability of response, $\Pr(\theta_q) = (1 + \exp[a_j(\theta_q - b_j)])^{-1}$, and then computing an observed binary response, x_{ijt} , for examinee i to item j at step t where $x_{ijt} = 1$ if $\Pr(\theta_q) < u_{ijt}$ and 0 otherwise where $u_{ijt} \sim U[0, 1]$.

The fixed length simulations using the content blueprint are run with a test of length 50 drawing from the various blueprint dimensions. The statement “100% blueprint match” is used to mean every one of the simulated tests has 50 total items and has item counts within the minimum and maximum boundaries for each dimension of the blueprint. Any deviation from this expectation is considered to not meet the blueprint. In all simulations, we compute the EAP as the provisional estimate and the final score is the MLE.

Exploring Different User-Defined Configuration Weights

We begin with a few logic tests to evaluate whether the algorithm can behave as a generally adaptive item selection algorithm consistent with adaptive theory. Specifically, we explore four conditions and capture a few measures of adaptivity. The first measure will be the root mean squared error (RMSE) at each true value of θ_q . The second will be a ratio of test information functions (TIFs) compared to a theoretical maximum (Wyse & McBride, 2021). The theoretical maximum is determined by computing item information for all items in the bank at θ_q and taking the sum over the 50 most informative items at each θ_q . This is only a “theoretical” maximum in the sense of what this specific simulated bank supports.

The first condition explored chooses items from the bank entirely randomly. This serves as a general baseline condition that has no adaptiveness to either the examinee or the test blueprint. Under this condition, we would expect large RMSE relative to adaptive conditions and match to blueprint at rates only equal to random chance. Recall that our definition of “meeting blueprint” is one where $N_{lg} \leq n_g \leq N_{ug} \forall g$ and $\sum_{g=1}^G n_g = 50$. Then, the probability of meeting blueprint with pure random draws can be determined from a multivariate hypergeometric distribution. This gives an expected probability of $\Pr(\text{meet}) = \left(\sum_{n_g \in \mathcal{S}} \prod_{g=1}^4 \binom{250}{n_g} \right) / \binom{1000}{50} = .119$ where $n_g \in \mathcal{S}$ denotes the set of all possible combinations of n_g determined from the ranges in Table (2) summing to 50 (e.g., 15+20+10+5, 7+19+10+14, etc).

The second condition is a linear-on-the-fly (LOFT) variant adhering to the test requirements defined in Table (2). In this condition, we would expect the algorithm to choose items based on these requirements and return a blueprint match rate of 100%. Because there is no adapting to examinee ability, LOFT chooses items randomly within each dimension as a stratified random

(a) RMSE of Four Simulated Conditions.

(b) Percentage of Theoretical Maximum.

Figure 1: Two Measures of Adaptivity

sampling approach, and so we expect the RMSE to be comparable in magnitude to the random condition. The third condition is purely item-adaptive and ignores the requirements in Table (2). In this condition, we expect match to blueprint rates equal to what would occur under random chance, although there may be a slight nudge away from randomness as items are matched with ability, and very small RMSE relative to non-adaptive conditions. The fourth condition is both item-adaptive and content-adaptive. Here we expect a 100% match to blueprint and RMSEs comparable in magnitude to the item-adaptive condition. These measures and the logic are similar to those used by van der Linden (2022).

Table (3) describes the different weight configurations used to yield each result. Additionally, the table shows the observed blueprint match rate from each of the simulated conditions. Figure (1a) shows the RMSE for each tested condition at the increments of θ_q used in the simulation and Figure (1b) shows the ratio of the TIFs. Results in both figures match *a priori* expectations for the RMSE and TIF ratios such that RMSEs for item-adaptive conditions are smaller than non-adaptive and the TIF ratios approach 100% for the adaptive conditions. Both suggest that the item selection algorithm described in Equation (1) achieves its two primary objectives. First, it is appropriately adapting on the examinee ability in Conditions (3) and (4) as observed in the smaller RMSE and larger TIF ratios. Second, small changes to the configuration weights achieve very different testing conditions and the match to blueprint rates indicates the content priority index achieves its objectives to adhere to a content blueprint.

Configuration Weight	Condition	Observed BP Match Rate
$\pi = 0, v = 0, h = 0$	Random Condition (Condition 1)	11.1%
$\pi = 0, v = 1, h = 1$	Linear on the Fly (LOFT) (Condition 2)	100%
$\pi = 1, v = 0, h = 0$	Item Adaptive (Condition 3)	12.3%
$\pi = 1, v = 1, h = 1$	Item and Content Adaptive (Condition 4)	100%

Table 3: User-Defined Configuration Weights for Simulation

The Potential of Information Switching

A second question explored is whether the notion of switching information after t steps offers benefits. In this portion of the simulation, we implement a stopping criterion using the conditional standard errors of measurement, $\sigma(\hat{\theta})$, such that each test terminates once $\sigma(\hat{\theta}_{it}) \leq .2$. Here five conditions are explored to assess this question. Condition 1 (MFI) uses the MFI for computing item information for all items administered. Condition 2 (Switch5) uses the KL procedure for the first five items and then switches to the MFI. Condition 3 (Switch10) uses the KL procedure for the first 10 items and then switches to the MFI. Condition 4 (CY) computes the KL information demonstrated by Chang and Ying (1996) where the limits of integration in Equation (5) are $\delta_t = .95/\sqrt{t}$. Last, Condition 5 (KL) uses the KL procedure for all items and the integration limits are $\delta_t = \sigma(\hat{\theta})$ for all steps. This concept has been explored to assess recovery on the estimated latent trait (Chang & Ying, 1996), but here we explore its impact on the test length.

Both Conditions 1 and 5 intend to provide upper and lower bound limits in terms of what we might expect in terms of total test length, given the limits of this specific item bank. If Conditions 2 or 3 offer any benefit, we expect to observe that the test would reach its termination criteria with a fewer number of test items relative to Condition 1 and approach the test length observed in Condition 5. Figure (2) shows the mean total number of test items for each of the conditions over values of θ_q . Here we observe that over the entire range of ability, Condition 2 reaches the termination criteria with fewer test items relative to Condition 1, typically between three to four fewer items, effectively reducing test length by an average of 8% relative to Condition 1. Additionally, we observe Condition 3 even further reduces test length beyond Condition 2 by about five more test items. It is useful to note that Conditions 4 and 5 perform similarly, which is sensible in that the examinee variance becomes smaller with increasing t , also causing the integration limits to center more on the observed score over iterations.

These simulations suggest the idea of switching how information is computed helps to reduce test length by capturing the uncertainty in the ability estimate early in the test. We almost certainly do not want to compute the KL for all items as this is computationally expensive relative to the MFI, although doing so seems to provide the shortest test length. Hence, by choosing a value of t where switching occurs, we approach the lower bound result of Condition 5 while reducing computational overhead as we switch to the MFI. This is a promising result for test developers wishing to even further reduce test length.

Exposure Control with Approximate Item Slopes

Here we test the idea of fixing the a -parameter to a pseudo-value for purposes of choosing items but use its actual estimate when generating scores, both provisional and final. We explore two conditions. In Condition 1, the estimated (actual) a -parameter is used and we measure the proportion of the bank that is used across all replicates in the simulation. In Condition 2, we fix $a_j = 1 \forall j$ for item selection and the proportion of the bank is again measured. Additionally, the final test score is captured as the MLE under both conditions and the RMSE and bias between both conditions is considered.

Figure (3a) illustrates the RMSE and Figure (3b) illustrates the bias at all true values of θ_q between both conditions. This figure shows that both conditions have no real practical differences in bias indicating the approximate a -parameter does not tend to compromise the final test score

Figure 2: Mean Total Number of Test Items by Condition.

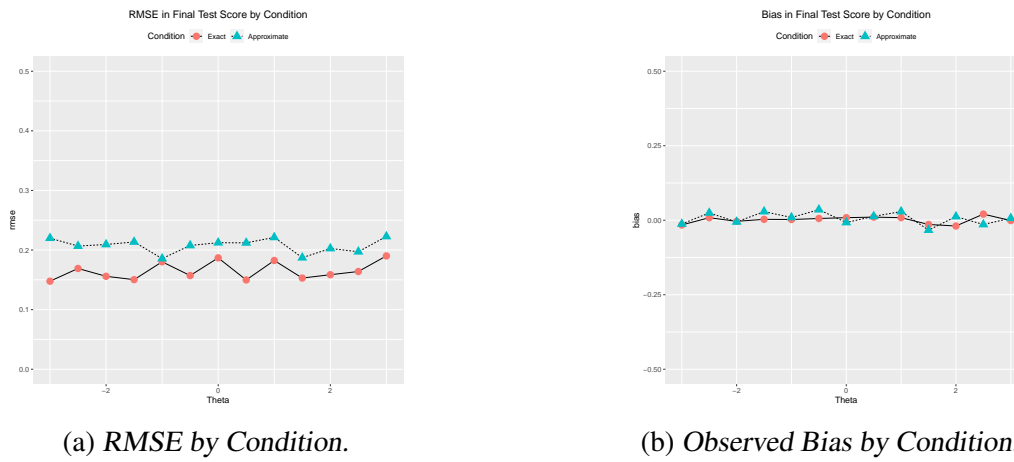

Figure 3: Impact of Pseudo Item Slope

negatively. There is a nominally larger RMSE for the pseudo-value condition relative to the exact condition, suggesting a small loss of measurement precision. Additionally, and importantly, the approximate a -parameter tends to use a larger proportion of the item bank. In Condition 1, the simulation shows the exact a -parameter results in the usage of 83% of the bank and the approximate a -parameter results in the usage of 96.4% of the bank. Hence, test developers may need to consider the trade-off between larger bank usage and a small loss of score precision.

Item Enemy Administration

Item enemies are sets (or pairs) of items that cannot be administered to an examinee on the same test form. Constructing fixed forms to avoid item enemies is straightforward as known pairs of enemies can be intentionally avoided in form construction. Here we demonstrate that the proposed algorithm can handle item enemy detection as a feature requirement without needing to create a bifurcated item bank. While we demonstrate this using item enemies, really the intent is to show that the feature requirements can be any arbitrary grouping structure defined by test developers. The potential here is virtually unlimited.

The example is constructed by forming a cluster of ten items that are enemies with each other.

Practically speaking, this means if one of these ten items is administered on a test form, then none of the remaining nine can appear on the same test form because they are enemies. We do this by forming a binary indicator in the item metadata associated with each item in the bank denoting a 1 if the items are in the enemy cluster group and 0 otherwise. Second, we modify the original test blueprint in Table (2) to have two new feature requirements. We add Group 1 with a min/max of 0/1 and Group 2 with a min/max of 49/50. The min/max of 0 to 1 for Group 1 instructs the algorithm to choose no more than one item from within this “enemy” cluster, but it can optionally choose none and Group 2 instructs the algorithm where to choose the other 49 (or 50) items.

We again simulate this new feature requirement which results in a 100% match to blueprint over all replicates and also no test form contains more than one item from Group 1 as expected by our new structure.

A Note on Items Crossed with Multiple Features

The modified blueprint used for the enemy example provides insight into how the algorithm can behave in complex ways. The term “Enemy Group” is used only as a descriptor for the example as those could be any conceivable grouping. The Group 1 min/max in that example is set to 0 and 1, respectively, to ensure no more than one item in Group 1 is administered together. However, a maximum larger than 1 would cause multiple items from within this group to be administered. Here we explain how the algorithm extends from nested features to scenarios where items are linked to multiple features.

First, when items are linked to one and only one feature, we say they are nested and the algorithm freely chooses n_g items from within each feature until test requirements are satisfied. For example, referencing Equation (1) and considering the nested simulation examples with four mutually exclusive dimensions, there would be four values of m_g , one for each dimension. So, the feature-relevant portion for the j th item (in simplified scalar form and ignoring item information for now) is $w_{j,d1}m_{d1} + w_{j,d2}m_{d2} + w_{j,d3}m_{d3} + w_{j,d4}m_{d4}$. Recall that larger values of m_g as defined by Equation (6) cause items linked to feature g to have greater appeal to the item selection algorithm and when a feature maximum has been realized, then $m_g = -p$. For example, suppose Dimension 4 has reached its max but the others have not. Then $m_4 = -p$ and items in Dimensions 1 to 3 would have positive values for m_g and be sorted higher in λ_{it} than any item associated with Dimension 4. We also remind the reader that w_j is used when items are linked to a single feature and w_j^* is used to denote a normalized value for items linked to multiple features.

In more complex scenarios, items can be linked with multiple features and not simply nested. For example, an item can simultaneously be linked with Dimension 1 and also Group 1 or Group 2. As such, there would now be six values of m_g , one for each of the four Dimensions and the two for Groups 1 and 2. So, the feature-relevant portion of the equation is $w_{j,d1}^*m_{d1} + w_{j,d2}^*m_{d2} + w_{j,d3}^*m_{d3} + w_{j,d4}^*m_{d4} + w_{j,g1}^*m_{g1} + w_{j,g2}^*m_{g2}$. Once Group 1 reaches its maximum, then $m_{g1} = -p$ and a negative term is added to items linked with this feature. However, if Group 2 has not reached its maximum, m_{g2} is a positive term added to items linked with this feature. For example, $w_{j,d1}^*m_{d1} - w_{j,g1}^*p$ is the value for the j th item linked to Dimension 1/Group 1 when Group 1 has reached its max and $w_{j,d1}^*m_{d1} + w_{j,g2}^*m_{g2}$ is the value for the j th item in Dimension 1/Group 2 when Group 2 has yet to reach its max. This is where the value of the penalty term, p , is used so that $w_{j,d1}^*m_{d1} - w_{j,g1}^*p < w_{j,d1}^*m_{d1} + w_{j,g2}^*m_{g2}$, thus causing items associated with Dimension 1/Group 2 to be sorted higher in the vector λ_{it} than those associated with Dimension 1/Group 1.

The addition of the min/max for Group 2 is not critical in this specific example as $w_{j,d1}^* m_{d1} - w_{j,g1}^* p < w_{j,d1}^* m_{d1}$ would be true causing the algorithm to prefer items in Dimension 1 that are not in Group 1. It is used here only to complete the example where there could be other min/max conditions for many more than two groups where this would be needed.

On-the-Fly Multistage

The simulations showcase the item-adaptive and the LOFT variants. We can creatively see the generalized nature of Equation (1) can also support on-the-fly multistage adaptive tests (Zheng & Chang, 2015), which sits in between these two ideas. Suppose the goal is to build smaller content-balanced forms that maximize information near a classification cutpoint. To form an example, let there be two ordered cutscores for classification, $\theta_1 < \theta_2$. Procedurally, building forms for MST would be computed as a special case of Equation (1) where information is fixed at $I'_j(\theta_1)$ over all t instead of updating $\hat{\theta}_{it}$ at each step, similar to the process described under the sufficiently adaptive strategy. A similar process would occur for θ_2 so that there is now an “easy” form and a “hard” form. In this way, we’re effectively building on-the-fly adaptive forms targeting a specific level of ability and examinees can be routed to other similarly built forms based on their scores after completing an initial form.

Discussion

Our effort has been to describe and demonstrate an item selection algorithm that has some potential to be generalizable and contribute to the body of algorithms in the heuristic family. The formalities of the algorithmic components have been defined alongside various decision details that could be used for its implementation. For completeness of presentation, we provide computational details so this work can stand alone as a specification resource for others wishing to implement Equation (2). Additionally, we demonstrate the behavior of the algorithm using simulated conditions in various ways. Our simulation results provide a few useful outcomes concerning our proposed approach. Mainly, our simulations show that the algorithm can behave generally enough to yield an array of custom test designs by simply manipulating the user-defined importance weights and configuring the priority index to achieve test developer-defined outcomes. Hence, the primary goal of developing a generalizable algorithm has some support as demonstrated in the scenarios provided here.

While some of the mathematical formalities may initially seem formidable, it is quite simple to implement and it has the potential to scale with large item banks, many test requirements, and large volumes of simultaneous test takers. Specifically, Equation (2) can be implemented directly or the alternative variant that reduces the search space can be used. The emphasis placed on scaling the algorithm is intended to address real-world applications of this algorithm’s potential in two specific ways. First, faster identification of the items needed to fulfill test requirements minimizes observed latency at the test-taker level. Not only does latency disrupt an examinee’s experience, but the vendor providing the test platform may also be subject to financial damages if they occur, what is commonly termed “liquidated damages”. Second, this algorithm scales efficiently so that when pushed into cloud-based structures for computing, it is likely to require fewer servers on demand, thus reducing monetary cost.

Our simulations explore only a subset of possible ideas but they are general enough to illustrate the potential use cases of the algorithm proposed. We can share that we have tested this algorithm with different item banks and different test requirements beyond those described in this manuscript and found it to satisfy test objectives if the item bank and blueprint requirements are reasonable. Our experience with severely constrained item banks is the algorithm will tend to meet blueprint requirements by overexposing certain items, although we would expect blueprint violations if the bank cannot support the requirements sufficiently.

While we purport that the algorithm is configurable and useful for different testing situations, we note that these claims are based on our experiences and the typical uses cited in the literature. The world of test designs and optimization approaches with machine learning technologies is rapidly changing and our claims are based on practices commonly used at this time. No single algorithm can accommodate every possible test design objective and we do not purport this approach will universally solve test construction problems. Hence, our main effort is to bring as much transparency to this algorithm as we possibly can and complement this manuscript with a publicly available software application. In this way, ideas not explored in our simulation can be directly tested by others to further identify its potential use cases as well as its limitations.

Going forward, a few ideas can be further explored. One idea to consider is whether optimization can be performed with complexity better than $\mathcal{O}(n \log n)$. Our description above requires sorting only because we use the randomesque approach. If instead we simply were to choose $\max \lambda_{it}$, then the algorithm would scale as $\mathcal{O}(n)$. The evaluation of algorithms is often missing from psychometric conversations, but with cloud-based systems now offering platforms for psychometric computing, such an evaluation is critical for cost containment. Cloud-based computing platforms indeed offer tremendous power and speed. However, this benefit comes with real monetary cost so we recommend that the first goal be to find the more optimal algorithm and only then pass the algorithm into a bigger computing environment. A second idea to explore is if other ways to compute item information could be used in the information switching idea to reduce test length even further. The idea we demonstrated has promise, and with concerns over testing time being generally too long, this could help reduce that concern. In particular, the newer notion of “through-year” designs in education could benefit from shorter, more precise tests, to provide diagnostic information at the examinee level. In fact, the State of Virginia in the U.S. passed legislation in 2021 requiring through-year designs with a CAT (Virginia State Statute §22.1-253.13:3, 2021).

It will be interesting to speculate on future CAT algorithms combined with automated item generation (AIG), item forecasting, and personalized learning platforms. Imagine an examinee sitting with a device that uses AIG to generate an item with forecasted item parameters, administer the item, collect and score the examinee’s response, repeat AIG to develop a new item based on the examinee’s response, and iterate this process until completion of the test. Then serve tailored, personalized learning content based on how the examinee performed on the test. Future integrations of large language models within psychometric platforms to support personalized learning algorithms have tremendous promise.

Acknowledgments

The authors would like to thank Drs. Jeff Dahlke, Richard Luecht, Insu Paek, Mark Reckase, and Daniel Segall for their suggestions and ideas on early versions of this manuscript. Additionally,

we thank the anonymous reviewers and the editor, Dr. Chun Wang, who offered very thoughtful suggestions and challenged us to extend our thinking to improve the quality of this work.
